Evidence for a Collective Intelligence Factor in the Performance of Human Groups

Anita Williams Woolley,1,2 Christopher F. Chabris,2,3 Alex Pentland,3,4 Nada Hashmi,3,5 Thomas W. Malone3,5

Psychologists have repeatedly shown that a single statistical factor—often called “general intelligence”—emerges from the correlations among people’s performance on a wide variety of cognitive tasks. But no one has systematically examined whether a similar kind of “collective intelligence” exists for groups of people. In two studies with 699 people, working in groups of two to five, we find converging evidence of a general collective intelligence factor that explains a group’s performance on a wide variety of tasks. This “c-factor” is not strongly correlated with the average or maximum individual intelligence of group members but is correlated with the average social sensitivity of group members, the equality in distribution of conversational turn-taking, and the proportion of females in the group.

As research, management, and many other kinds of tasks are increasingly accomplished by groups—working both face-to-face and virtually (1–3)—it is becoming ever more important to understand the determinants of group performance. Over the past century, psychologists made considerable progress in defining and systematically measuring intelligence in individuals (4). We have used the statistical approach they developed for individual intelligence to systematically measure the intelligence of groups. Even though social psychologists and others have studied for decades how well groups perform specific tasks (5, 6), they have not attempted to measure group intelligence in the same way individual intelligence is measured—by assessing how well a single group can perform a wide range of different tasks and using that information to predict how that same group will perform other tasks in the future. The goal of the research reported here was to test the hypothesis that groups, like individuals, do have characteristic levels of intelligence, which can be measured and used to predict the groups’ performance on a wide variety of tasks.

Although controversy has surrounded it, the concept of measurable human intelligence is based on a fact that is still as remarkable as it was to Spearman when he first documented it in 1904.

People who do well on one mental task tend to do well on most others, despite large variations in the tests’ contents and methods of administration. In principle, performance on cognitive tasks could be largely uncorrelated, as one might expect if each relied on a specific set of capacities that was not used by other tasks. It could even be negatively correlated, if practicing to improve one task caused neglect of others. The empirical fact of general cognitive ability as first demonstrated by Spearman is now, arguably, the most replicated result in all of psychology.

Evidence of general intelligence comes from the observation that the average correlation among individuals’ performance scores on a relatively diverse set of cognitive tasks is positive, the first factor extracted in a factor analysis of these scores generally accounts for 30 to 50% of the variance, and subsequent factors extracted account for substantially less variance. This first factor extracted in an analysis of individual intelligence tests is referred to as general cognitive ability, or g, and it is the main factor that intelligence tests measure. What makes intelligence tests of substantial practical (not just theoretical) importance is that intelligence can be measured in an hour or less, and is a reliable predictor of a very wide range of important life outcomes over a long span of time, including grades in school, success in many occupations, and even life expectancy.

By analogy with individual intelligence, we define a group’s collective intelligence (c) as the general ability of the group to perform a wide variety of tasks. Empirically, collective intelligence is the inference one draws when the ability of a group to perform one task is correlated with that group’s ability to perform a wide range of other tasks. This kind of collective intelligence is a property of the group itself, not just the individuals in it. Unlike previous work that examined the effect on group performance of the average intelligence of individual group members, one of our goals is to determine whether the collective intelligence of the group as a whole has predictive power above and beyond what can be explained by knowing the abilities of the individual group members.

The first question we examined was whether collective intelligence—in this sense—even exists. Is there a single factor for groups, a c factor, that functions in the same way for groups as general intelligence does for individuals? Or does group performance, instead, have some other correlational structure, such as several equally important but independent factors, as is typically found in research on individual personality?

To answer this question, we randomly assigned individuals to groups and asked them to perform a variety of different tasks. In Study 1, 40 three-person groups worked together for up to 5 hours on a diverse set of simple group tasks plus a more complex criterion task. To guide our task sampling, we drew tasks from all quadrants of the McGrath Task Circumplex, a well-established taxonomy of group tasks based on the coordination processes they require. Tasks included solving visual puzzles, brainstorming, making collective moral judgments, and negotiating over limited resources. At the beginning of each session, we measured team members’ individual intelligence. And, as a criterion task at the end of each session, each group played checkers against a standardized computer opponent.

The results support the hypothesis that a general collective intelligence factor (c) exists in groups. First, the average inter-item correlation for group scores on different tasks is positive (r = 0.28) (Table 1). Next, factor analysis of team scores yielded one factor with an initial eigenvalue accounting for more than 43% of the variance (in the middle of the 30 to 50% range typical in individual intelligence tests), whereas the next factor accounted for only 18%. Confirmatory factor analysis supported the fit of a single latent factor model with the data (χ² = 5.85, P = 0.13, df = 5; CFI = 0.98, NFI = 0.89, RMSEA = 0.03).

In addition, for a subset of the groups in Study 2, we included five additional tasks, for a total of ten. The results from analyses incorporating all ten tasks were also consistent with the hypothesis that a general c factor exists (see Fig. 2). The scree test clearly suggests that a one-factor model is the best fit for the data from both studies. Furthermore, parallel analysis (13) suggests that only factors with an eigenvalue above 1.38 should be retained, and there is only one such factor in each sample. These conclusions are supported by examining the eigenvalues both before and after principal axis extraction, which yields a first factor explaining 31% of scores of individual group members are not significantly correlated with c (r = 0.19, not significant (ns); r = 0.27, ns, respectively) and not predictive of criterion task performance (r = 0.18, ns; r = 0.13, ns, respectively). In a regression using both individual intelligence and c to predict performance on the criterion task, c has a significant effect (β = 0.51, P = 0.001), but average individual intelligence (β = 0.08, ns) and maximum individual intelligence (β = 0.01, ns) do not (Fig. 1).

In Study 2, we used 152 groups ranging from two to five members. Our goal was to replicate these findings in groups of different sizes, using a broader sample of tasks and an alternative measure of individual intelligence. As expected, this study replicated the findings of Study 1, yielding a first factor explaining 44% of the variance and a second factor explaining only 20%. In addition, a confirmatory factor analysis suggests an excellent fit of the single-factor model with the data (χ² = 5.85, P = 0.13, df = 5; CFI = 0.98, NFI = 0.89, RMSEA = 0.03).

Fig. 1. Standardized regression coefficients for collective intelligence (c) and average individual member intelligence when both are regressed together on criterion task performance in Studies 1 and 2 (controlling for group size in Study 2). Coefficient for maximum member intelligence is also shown for comparison, calculated in a separate regression because it is too highly correlated with individual member intelligence to incorporate both in a single analysis (r = 0.73 and 0.62 in Studies 1 and 2, respectively). Error bars, mean ± SE.
Fig. 2. Scree plot demonstrating the first factor from each study accounting for more than twice as much variance as subsequent factors. Factor analysis of items from the Wonderlic Personnel Test of Individual intelligence administered to 642 individuals is included as a comparison.

Many previous studies have addressed questions like these for specific tasks, but by measuring the effects of specific interventions on a group’s c, one can predict the effects of those interventions on a wide range of tasks. Thus, the ability to measure collective intelligence as a stable property of groups provides both a substantial economy of effort and a range of new questions to explore in building a science of collective performance.
